### **Abstract**

We propose a framework for the development of vision systems that incorporate, along with the executable programs, the syntactic, semantic and strategic knowledge required to obtain optimal performance. In this approach, the user provides the input data, specifies the vision task to be performed, and then provides feedback in the form of qualitative evaluations of the result(s) obtained. These assessments are interpreted in a knowledge-based framework to automatically select algorithms and set parameters until results of the desired quality are obtained. In this manner the vision system is given the capacity to tune itself for optimal performance. A system thus trained on a small subset of the input data can then be run autonomously on the remaining data in a batch mode. This approach is illustrated on two real applications, analysis of Synthetic Aperture Radar (SAR) imagery, and detection of vehicles in aerial photographs.

## 1 Introduction

Vision systems used in challenging operational environments should satisfy the conflicting requirements of flexibility and convenience. Flexibility is the ability to accommodate variations in operating conditions. Convenience pertains to the ease of operation of the system by a user who is not familiar with the technical details of the algorithms employed.

Variations in image characteristics are caused by a number of factors such as weather, lighting conditions and image acquisition parameters. A vision system should accommodate a reasonable amount of such variation, and should degrade gracefully as the image characteristics deviate from the ideal. One can allow for such variations by providing alternative algorithms for each task, as well as tuning parameters for each algorithm. In most cases, a judicious choice of algorithms and parameters provides results of acceptable quality under a wide range of operating conditions.

Vision systems in the real world are often utilized by users who, while competent in the visual analysis of images, may not be familiar with the technical details of the algorithms they employ. It is not reasonable to expect the user functioning in an operational situation to select and tune the algorithms for the task (s)he is required to perform. This function is best left to the designer (the vision specialist) who may not be available during the system's operation. It is thus obvious that a vision system that provides *flexibility* in the choice of algorithms and parameter values may not be very *convenient* for the user to utilize.

In order to achieve the conflicting goals of flexibility and convenience, we propose a knowledge-based framework to partially or fully automate the reasoning employed by the vision specialist in obtaining satisfactory results from the system. The proposed framework is implemented using the LAMA platform [13, 20]. The original vision algorithms are semantically integrated into this framework. The integrated system, shown schematically in Fig. 1, can then be made available to the user. This type of system is capable of self-tuning, i.e. adapting to changes in data characteristics and performance requirements with minimal external intervention. Any interaction with the user is in terms of qualitative evaluations of results, and not in terms of algorithms and parameters. In many situations, the same processing task is performed on a large data set consisting of hundreds or even thousands of images. In such cases, the system can be interactively tuned on some representative images, and once satisfactory performance is achieved, can then be used with fixed settings for batch processing of the remaining images in the data set.

The organization of this paper is as follows. Section 2 briefly reviews related work. Section 3 discusses the basic concepts of knowledge-based control. Section 4 presents the LAMA platform. In Sections 5 and 6, results of applying our methodology to two candidate applications (Synthetic Aperture Radar (SAR) image analysis and vehicle detection in aerial imagery) are presented. These applications, developed at the University of Maryland, were selected firstly because they address interesting and non-trivial problems, and secondly because their developers were available to provide the required expertise, indispensable for constructing the

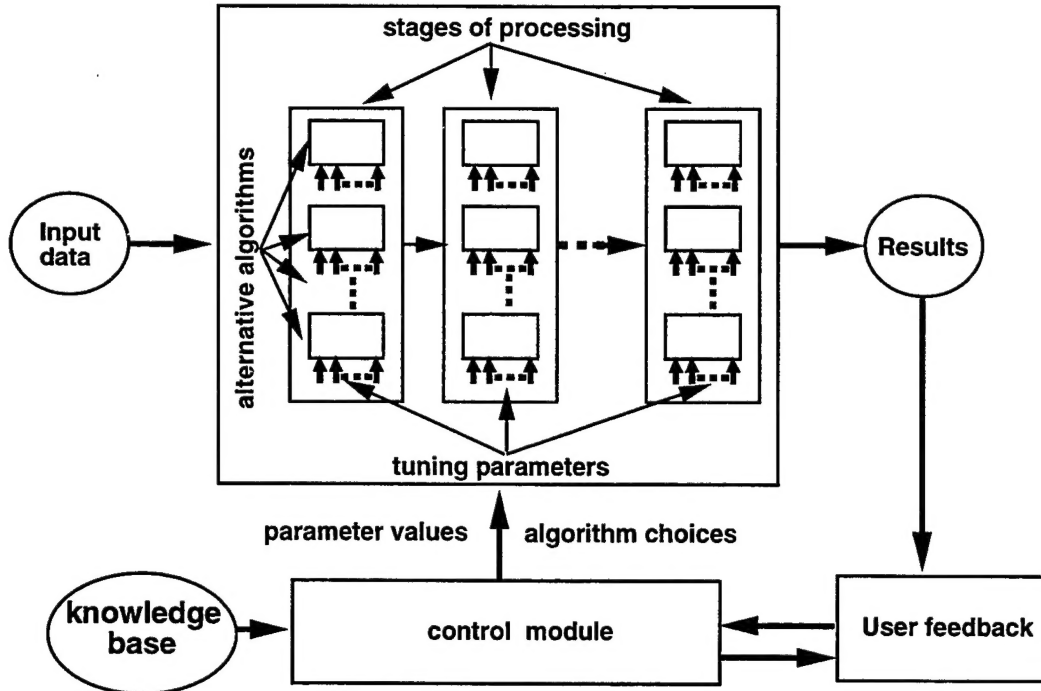

Figure 1: Architecture of a self-tuning vision system. The vision system has a number of stages of processing, with different possible algorithm choices at each step. Each algorithm may have one or more tunable parameters. The user evaluates the result(s) of processing, and the control module uses this feedback to change algorithms or parameters in order to improve the results.

knowledge bases. The final section contains the conclusions resulting from our work, as well as a list of areas for further investigation.

## 2 Previous work

As vision algorithms and systems have grown in power and complexity during the past few decades, there has been a corresponding growth in software platforms tailored to vision system development. Traditional methods range from graphical script generators, to vision toolkits, to object-oriented protocols for data and program interchange. The emphasis is on abstracting the types of objects and computational geometries used in image understanding into useful programming constructs [12]. One of the objectives is to enable the rapid design of algorithms using a tool-box of pre-existing constructs, and prototyping of longer processing chains by linking simpler elements together. The user is often provided with a visual programming environment (VPE), which enables him or her to mix-and-match between the available methods. For the most part, these systems offer only *syntactic integration* of vision programs. They provide a means to integrate code and usage syntaxes, but do not provide a means to incorporate further knowledge about the programs.

Knowledge-based techniques can be used in various ways in the development of vision sys-

tems. For an excellent survey of this topic, see [6]. Knowledge-based systems, also known as expert systems, have been traditionally used for the high-level interpretation of images, and for specific vision tasks such as segmentation (e.g. [14]). They incorporate mechanisms for the spatial and temporal reasoning that is characteristic of intermediate- and high-level image understanding. These knowledge-based systems are tailored towards specific tasks, and are usually not generalizable to other tasks.

The work presented in this paper is different from the above two approaches (syntactic integration systems and expert systems for specific vision tasks) in the sense that it proposes a general-purpose framework for knowledge-based control of vision systems. The approach can be used to develop knowledge-based semi-autonomous systems for any vision application. This is a continuation of the work reported in [5, 17].

Some of the early work with a similar motivation is reported in [8, 18, 11]. More recently, this problem has been addressed in the context of the VIDIMUS project [1], with the aim of developing an intelligent vision environment for industrial inspection. A knowledge-based system (VDSE) was built within this environment, which can automatically configure a vision system for a given inspection problem. The automatic generation of an image processing script based on a user request and a knowledge-based model of an application domain is addressed in [4]. In [7] vision algorithm control is modeled as a Markov decision problem. This model is used to automatically assemble object recognition programs from existing vision algorithms. In [15, 16] a context-based vision paradigm is proposed, where the basic aim is to use contextual information to select methods and parameters in a vision application. The authors emphasize the need for explicitly encoding semantic knowledge about vision algorithms such as assumptions about their use and their inherent limitations. The use of contextual information derived from site models to construct control patches for the self-tuning of vision algorithms is discussed in [2].

### 3 Knowledge-based control

In a typical vision application, a number of stages of processing are involved in going from the raw input data to the final result, as shown in Fig. 1. Typically, at each stage of processing a number of alternative algorithms can be employed. Each of these algorithms, in turn, may have one or more tunable parameters. These parameters may be continuously variable, or may take discrete sets of values. Often, due to uncertainty in the data and in the problem model, it is not possible to predict beforehand if a given algorithm sequence will produce the desired result for a certain parameter setting. It may be necessary to start with a rough guess as to the parameters, execute the algorithm sequence, examine the results, and if necessary, modify the parameter values or the selection of algorithms, and repeat the procedure until results of the desired quality are obtained.

In this section, we examine the types of knowledge used by a vision specialist (and therefore required for knowledge-based control), and the implications for the design of self-tuning vision systems.

### 3.1 Smart modules

From a problem-solving perspective, the task of solving a vision problem using a given set of algorithms involves three types of knowledge: syntax, semantics and strategy. Syntactic knowledge is information about input and output data types and formats, input parameters, command-line arguments, etc. Information such as memory required may also be considered as syntactic knowledge. Semantic knowledge is the vision specialist's expertise about the characteristics of the algorithms, result evaluation, assembly of algorithms for a given task, etc. Strategic knowledge pertains to the high-level decisions that should be made about result evaluation (by the system, by the user, or not at all) and failure handling (repair failure at the current module or at another place in the chain of processing, repair failure by parameter tuning or by algorithm reselection, etc.).

The objective of knowledge-based control is to provide a suitable framework for "packaging" algorithms using the three types of knowledge described above. Conceptually, as shown in Fig. 2, raw programs are wrapped with layers of syntactic, semantic and strategic knowledge to form "smart" modules. This is done in a recursive fashion for more complex tasks—smart modules can be connected sequentially (Fig. 3), in parallel (Fig. 4), or selectively (Fig. 5), and the ensemble is then re-wrapped.

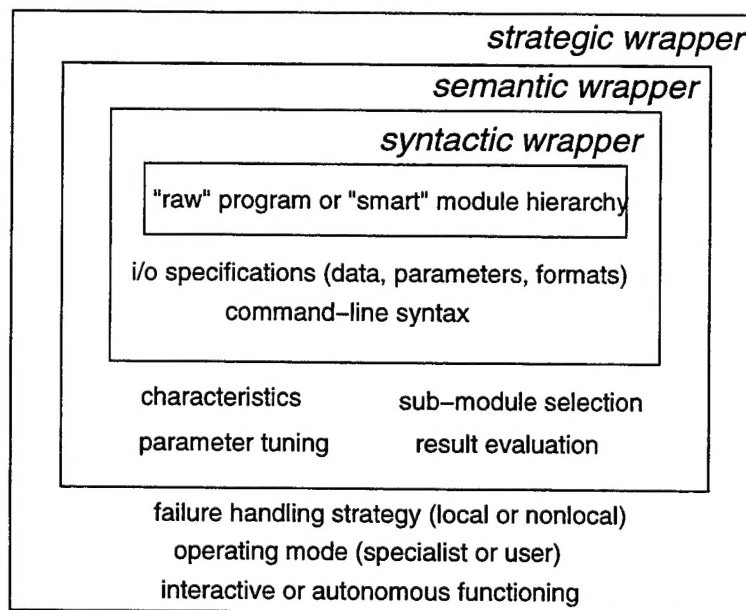

Figure 2: Packaging a vision algorithm into a "smart" module. A "raw" executable program is not useful to anyone except the specialist who designed and implemented it. In order for another person, particularly a non-specialist, to use the program, it must be accompanied by some knowledge about how to run it, how to evaluate its results, how to tune it, etc. Smart modules can themselves be connected in various ways and re-packaged for more complex tasks.

Figure 3: A module with a sequential decomposition into sub-tasks. Execution of Module 1 implies sequential execution of Modules 1.1 through 1.n.

Figure 4: A module with a parallel decomposition into sub-tasks. Execution of Module 1 implies execution in parallel of Modules 1.1 through 1.n.

Figure 5: A module with different possible realizations. Execution of Module 1 implies the execution of one of Modules 1.1 through 1.n.

### 3.2 Self-tuning

Self-tuning is the ability of the vision system to select the appropriate algorithms and parameter values based on the input data, contextual information, and feedback from the user in the form of result evaluations. In most cases, the selection of algorithms may be performed, before any data processing has taken place, based on the contextual information alone [15]. Parameter tuning, on the other hand, is dependent on the characteristics of the specific data set. It has to be interleaved with the processing of the data, based on the operator's evaluation of the results.

Consider a vision system  $A$  composed of  $m$  stages, with  $n_i$  parameters in the  $i$ th stage:

$$A = A_1 A_2 \dots A_i \dots A_m$$

where each  $A_i$  is of the form

$$A_i = A_i(p_{i1}, p_{i2}, \dots, p_{in_i})$$

As shown in Fig. 6 the entire vision system can be regarded as consisting of a single algorithm  $A(p_1, p_2, \dots, p_N)$ . The  $N$  parameters that tune this "black box" algorithm are the  $\sum_{i=1}^m n_i$  parameters of the  $m$  individual stages. We refer to a specific setting of these  $N$  parameters as an operating point (OP). We define an *acceptable* operating point as a parameter setting that yields satisfactory performance for the given data set. Our basic assumption is that there exists at least one acceptable operating point (or, in the case of continuous-valued parameters, operating region). In general, the default parameter setting will not be an acceptable one. The

### 3.3 Modes of operation

Any vision task  $A$  can be hierarchically decomposed into a set of subtasks  $A_1-A_m$ , each of which (say  $A_i$ ) may be decomposed further into subtasks  $A_{i1}-A_{im_i}$  and so on. For instance, a typical vision system may consist of a top-level module  $A$ , consisting of sub-modules  $A_1$  and  $A_2$ , and these may be composed of elementary subtasks  $A_{11}$ ,  $A_{12}$ ,  $A_{21}$ , and  $A_{22}$ . In our model, attached to each (sub)task  $A_{...}$  at any level in the hierarchy is a *strategy*  $T_{...}$  which contains all the specialist's knowledge about the module: how/when it should be used, how to evaluate its performance, and how to adjust it if improved performance is required. Depending on the strategies available, this type of a system can function in one of two modes: the specialist mode or the user mode.

In the specialist mode, shown in Fig. 8, all the strategies at every level of the hierarchy are available. In other words, results at every stage, including the intermediate ones, are available for evaluation by the specialist. This is applicable to the test phase when the specialist is in the process of testing the functioning of the system. In the user mode, shown in Fig. 9, only the top-level strategy  $T$  is directly available and only the results of the final stage are available for evaluation by the user. This mode is designed for the operational phase. From a control-theoretic viewpoint, a self-tuning vision system can be regarded as a closed-loop system where the observer is the user, who provides feedback in the form of result evaluations. This feedback can be either at the highest level (corresponding to the user mode), or at all levels (corresponding to the specialist mode).

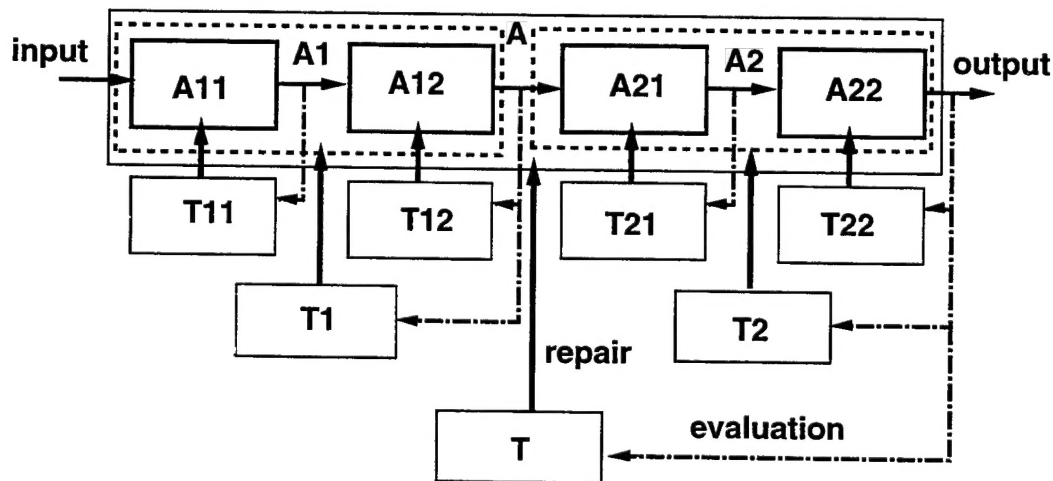

Figure 8: Specialist tuning mode for a three-level vision system. The results of the modules  $A$ ,  $A_1$ ,  $A_2$  and  $A_{11}-A_{22}$  and the corresponding strategies  $T$ ,  $T_1$ ,  $T_2$  and  $T_{11}-T_{22}$  are available.

In the specialist mode, the availability of intermediate results enables linear planning for the fine-grain local optimization of algorithms. The user mode, however, necessitates the use of

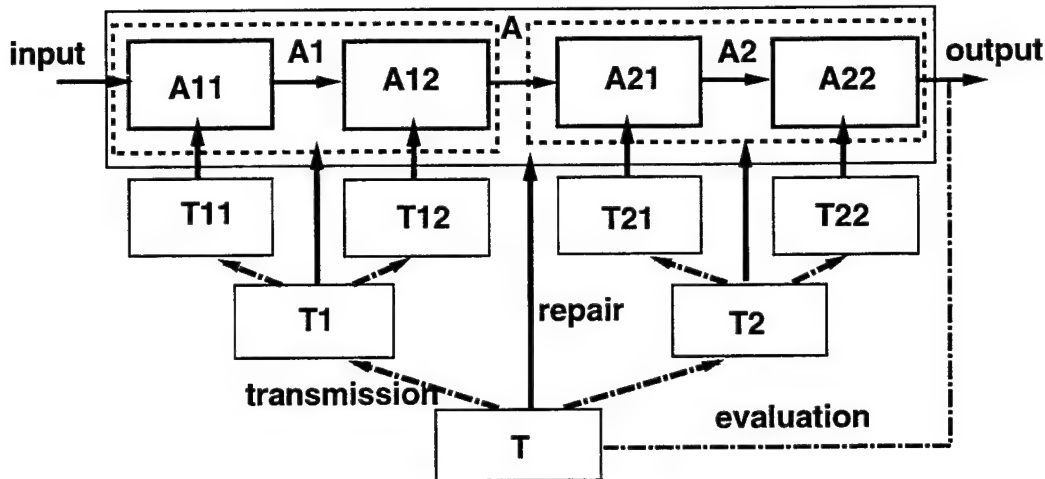

Figure 9: User tuning mode for a three-level vision system. Only the results of the top-level module A and the corresponding strategy T are directly available. The strategies  $T_1$ ,  $T_2$  and  $T_{11}$ – $T_{22}$  are available only indirectly through message transmission.

more complex reasoning, since only the final result is available, based on which any algorithm at any stage of the processing may have to be retuned.

### 3.4 Result evaluation

In the user mode, the vision system is tuned based on the evaluation of results by the user. We can define two types of result evaluation: general and specific. General evaluation consists of qualitative global judgments about algorithms and results (“too many false alarms”, “too many missed detections at road intersections”, etc.). Specific evaluation, on the other hand, pertains to particular objects or regions in the result (“this airplane is a false alarm”, “this portion of the image contains too many false alarms”, etc.). It can be qualitative or quantitative in nature. An example of each type of evaluation is shown in Fig. 10.

Both types of evaluation have their advantages and drawbacks. Specific evaluations are simple, intuitive, and precise. The user is not expected to make any detailed analysis of the results. Further, for certain applications such as target detection, specific evaluations provide a very rich form of feedback to the control engine. However, they are difficult to deal with in a general-purpose framework, since they require mechanisms for reasoning and for user interaction that are application-dependent. This makes separation of the application from the knowledge base more difficult. General evaluations are of a more complex nature than specific evaluations, since they require more detailed feedback from the user on the types of errors present in the output. However, they are more suitable for a general-purpose framework, since they do not require any special interaction or reasoning mechanisms, and are relevant to all types of vision

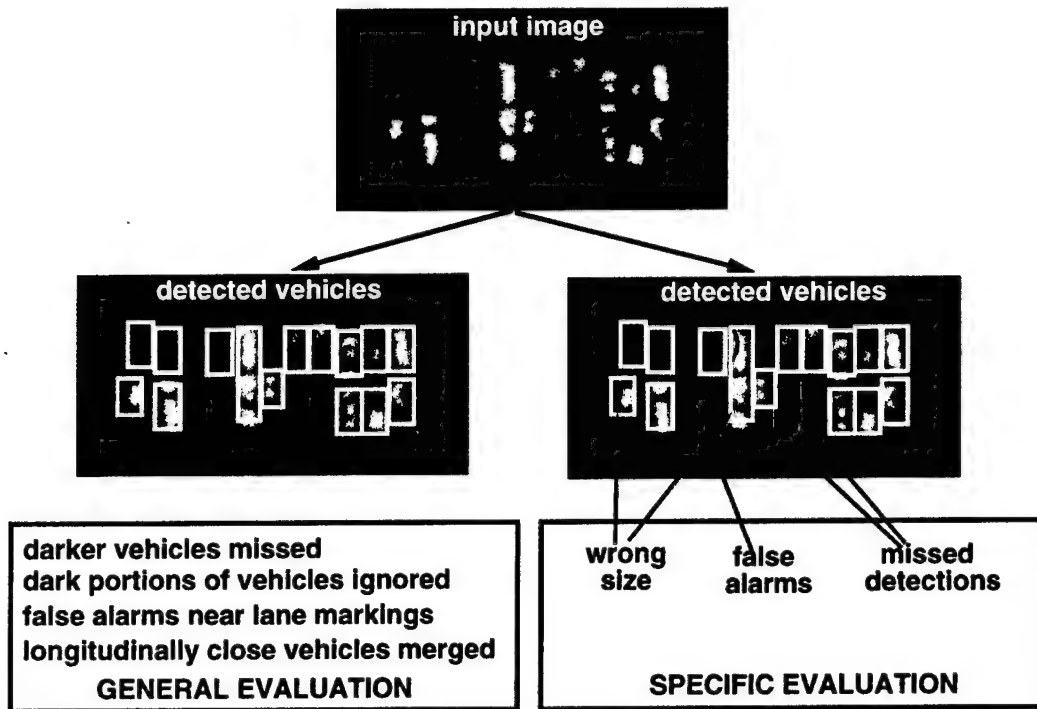

Figure 10: Example of the two types of result evaluation. The application here is the detection of vehicles in an aerial image. The user can provide feedback either in the form of general remarks about the overall result, or in more specific terms.

problems. In this paper, we deal primarily with general evaluations.

#### 4 The LAMA platform

LAMA is a methodology as well as a general-purpose platform for developing intelligent applications, consisting of a kernel library, a knowledge base description language called YAKL (Yet Another Knowledge-base Language), verification and validation (V & V) facilities, a graphical user interface and other tools, as shown in Figure 11. A complete description of LAMA is beyond the scope of this paper; the interested reader is referred to [20]. For our purposes, LAMA may be viewed as an architecture based on frames and rules for encapsulating the problem-solving knowledge of the vision specialist.

A vision application developed using LAMA consists of a set of pre-existing algorithms (also referred to as programs, modules or methods), a knowledge base (KB) on using these algorithms, and a control (supervision) engine. A vision *functionality* is the abstract representation of a vision task. It is realized in a concrete form by one or more *operators* corresponding to it. An operator may be either simple, corresponding to an executable program, or composite, represented by a predefined skeletal plan. A skeletal plan describes a network of connections between operators (choice, sequence, repetition, etc.) for realizing a given functionality. The description of an operator contains information about its arguments (name, type, range, default

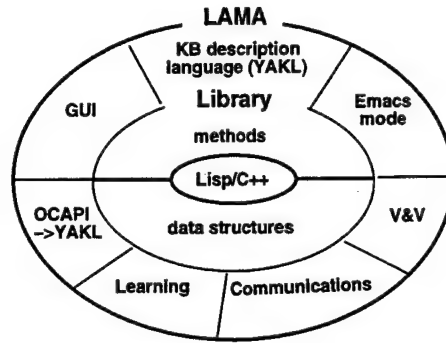

Figure 11: The LAMA platform

values, etc. of the input data, output data and parameters), semantic information about its applicability (in the form of pre- and post-conditions), as well as criteria for parameter initialization, result evaluation, etc. For operators corresponding to real executable programs the calling syntax is also provided. The structure of operators is shown in Fig. 12.

The functioning of the control engine (Fig. 13) can be decomposed into a number of phases: *planning* and *execution* of programs, *evaluation* of the results, and *repair*, as shown in Fig. 13. The planning step first builds a plan, or part of a plan, which is then executed. The results of execution are then assessed in the evaluation step. If the assessments are positive, the planning process continues. If failures are detected, the repair step invokes the appropriate remedial measures which may either result in re-execution or re-planning of any part of the hierarchy. The planning, evaluation and repair steps are discussed in greater detail in the following sections.

#### 4.1 Planning

The basic planning mechanism used is hierarchical script-based planning. A plan is a set of steps to attain the desired vision objective. It is similar to the block schematics often used in the design of signal processing algorithms, but is different in two ways:

- (a) **Plan hierarchy:** each "box" in the plan can be a complex vision task, with its own plan,
- (b) **Plan abstraction:** the components of the plan represent abstract vision tasks, and not specific algorithms or programs. During execution, *choice rules* are used for selection of the operator best suited for the task at hand. They are of the form:

if

the data have property  $x$

AND context field  $f$  has value  $y$

AND the request has a constraint  $z$

then

choose an operator with characteristic  $b$

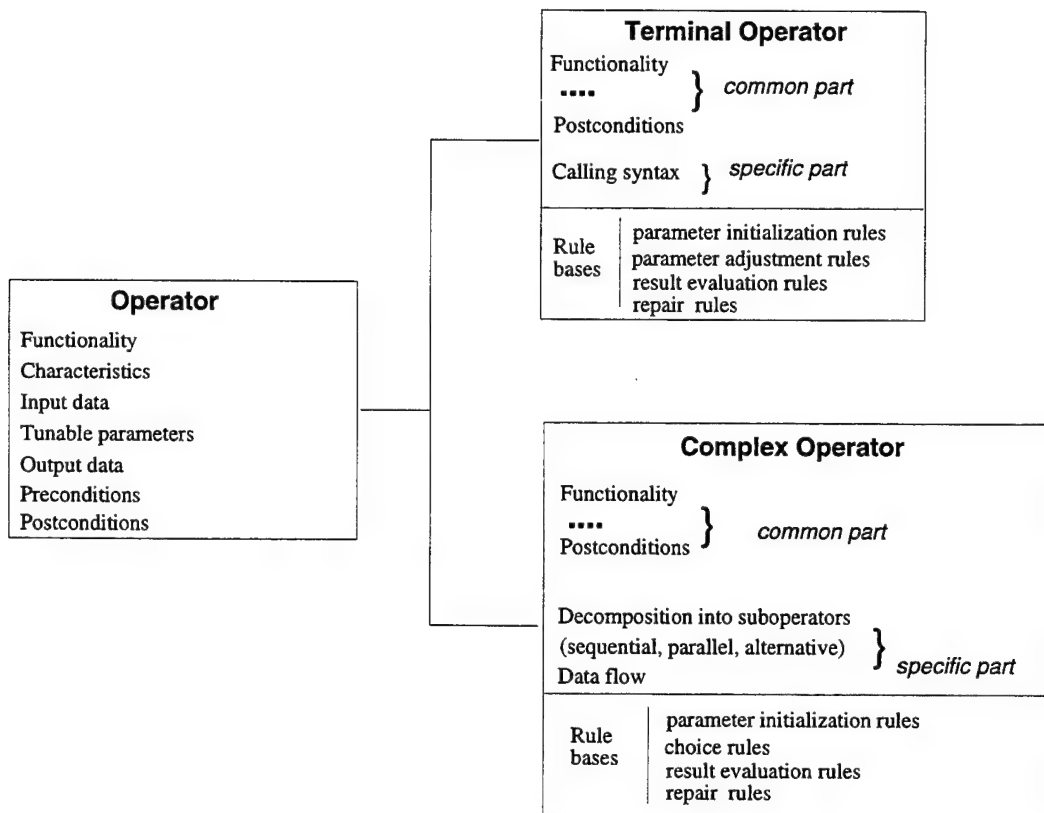

Figure 12: Structure of operators in LAMA. There are two types of operators, simple and complex. Simple operators are “packaged” forms of executable programs, while complex operators have an associated decomposition.

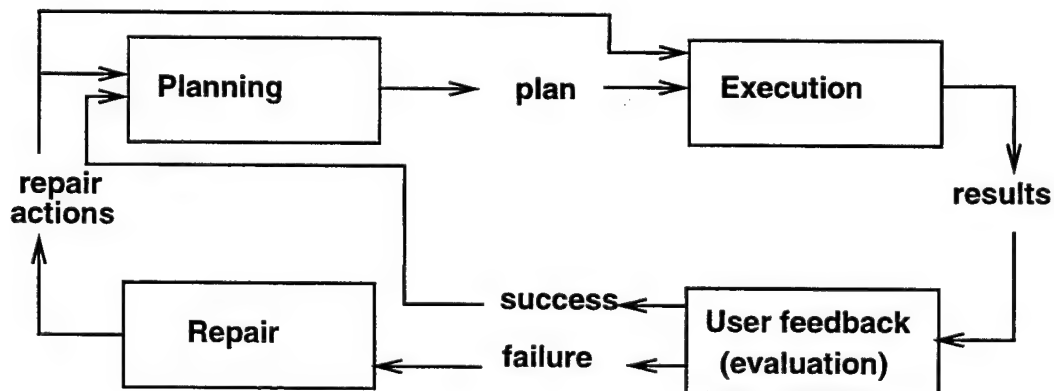

Figure 13: Control strategy

AND do not choose operator  $w$

(The above example shows only some of the possible types of premises and actions in a choice rule. Many other types of premises and actions are possible, for choice rules as well as for the three other kinds of rules described later.)

Once an operator is selected, it is initialized using *initialization rules*, of the form:

if

the data have property  $x$

AND context field  $f$  has value  $y$

then

set parameter  $p$  to value  $f(y)$

#### 4.2 Evaluation

The performance of an operator is analyzed using *evaluation rules*, which are of the form:

if

the output does not satisfy criterion  $c$

then

judge *plan entity* to have *some quality*

declare failure

The "plan entity" could be the current operator, a result of processing, or in general, any plan element in the hierarchy. Many other types of evaluation are possible, using information about the previous evaluation, about the number of times the operator has been (unsuccessfully) executed, about whether the result is better or worse than before, etc.

#### 4.3 Repair

Failure handling in LAMA is performed either locally inside the operator, or nonlocally by message transmission to another part of the plan.

Local failures are handled by parameter tuning using *repair* and *adjustment rules*. A repair rule for local failure-handling is usually very simple, of the form:

if

true

then

re-execute

When this rule is applied, the operator is re-executed, invoking one or more adjustment rules of the form:

**if**

result  $r$  has quality  $q$

**then**

adjust parameter  $p$  using method  $m$

When the failure of the current operator is caused by the (undetected) failure of another, the repair strategy employs message transmission from the current operator to the offending one. The repair rule in this case is of the form:

**if**

result  $r$  has quality  $q$

**then**

send message  $m$  to operator  $o$

The control then switches to operator  $o$ , whose failure-handling strategy is then activated, based on the message  $m$  that has been sent to it.

#### **4.4 Integrating an application into LAMA**

Vision applications typically consist of a number of executable programs with associated syntactic, semantic and strategic knowledge, as described in Section 3.1. The mechanisms for planning, evaluation and repair provided by LAMA enable us to package a given vision system into an ensemble of smart modules, enabling the user to obtain optimal performance with minimal intervention. A knowledge representation language, YAKL, is employed for this purpose. Mechanisms are provided to test the consistency of the knowledge base thus created [20]. A number of different control engines are available for running the integrated application. In our work, we use the PEGASE engine [21] which provides hierarchical and skeletal-based planning interleaved with control of execution. A GUI is provided for examining the knowledge base as well as for monitoring the application during execution.

The following two subsections describe how to build a LAMA/PEGASE knowledge base (KB) for an application, and how to run the integrated application.

##### **Building a knowledge base**

The first step is the construction of a set of skeletal plans for the application. A plan consists of an operator hierarchy, where the top-level operator solves a given vision task. The task performed by this operator is then recursively decomposed into sub-tasks, each with an associated complex or simple operator, until the lowest levels of the operator hierarchy contain only

simple operators. Complex operators have an operator decomposition associated with them, whereas simple operators specify the calling syntax of the associated program. A goal instance is created corresponding to the top-level operator functionality.

The next step is the creation of the rules which express the strategy of the specialist in executing a plan. The LAMA architecture enables the systematic expression of the "rules of thumb" and "approximate reasoning" which are crucial to successful problem-solving. This is done by means of the five types of rules discussed earlier. A mixture of numeric and symbolic reasoning may be needed for all four types of rules. Choice rules, being the simplest, are defined first. They use the values of context fields, data definitions, constraints in the request, etc. to select an operator from among the choices available. Initialization rules are defined next. These may be somewhat more difficult, in that they have to formalize the "rough initial guesses" that the specialist makes before starting an vision task. Adjustment rules are then defined for operators which have adjustable parameters. Step sizes for parameters have to be carefully chosen so that the change in the behavior of the algorithm is neither too sudden nor too gradual. Then evaluation rules are defined. This is a rather difficult task, since the question "Are the results good enough?" is often subjective, and appropriate quality measures may not be readily available. However, a close examination of the specialist's strategy often reveals hidden reasoning capable of being expressed in concrete terms as evaluation rules. Finally, the repair rules are defined. These rules determine the overall failure-handling strategy, and are crucial to the success of the application.

### **Running an application in LAMA/PEGASE**

The solving of a problem starts with the creation of a request, which states the functionality, the data on which this is to be achieved, and the context in which the problem is being solved. Using choice rules, the available operators for the functionality are rank-ordered. The best operator is selected, and executed on the given data after the operator's initialization rules have been applied. If the operator is a simple one, this corresponds to the execution of the corresponding program. If it is a composite one, requests for its sub-tasks are created, and a tree of requests is created. Requests are chosen from this tree and executed depending on their sequencing. If the mode of execution control calls for it, the results of executing a request are judged using evaluation rules, and in the event of a failure, either the same operator is re-executed after its parameters have been adjusted using the relevant rules, or the next best operator is applied. In the event of successful execution, the next request in the tree is selected for execution. This continues, and the execution terminates when the tree of requests is empty.

The next two sections illustrate our approach using two real applications. The first application, Synthetic Aperture Radar (SAR) image analysis, illustrates the specialist mode of self-tuning, while the second application, vehicle detection, illustrates the user mode.

## 5 Example: SAR Image Analysis

This application is based on the work of Kuttikkad and Chellappa [9]. Its goal is to analyze a SAR image to identify semantic objects such as targets, buildings, roads, and trees, and to segment the remaining parts of the image into various categories such as grass, water and bare ground. The first step is the detection of regions of high backscatter using a Constant False Alarm Rate (CFAR) technique [9]. In the next step non-target pixels in the image are classified as grass, tree, bare ground, road or shadow using a Maximum Likelihood (ML) approach. Training data obtained from other images of similar scenes is employed. This is a preliminary classification, using no high-level information whatsoever. A large percentage of the pixels are likely to be misclassified.

Shadow regions are detected and then eroded and grown using morphological operations. The same is done for pixels classified as road. Very small regions of either class are eliminated, and the rest are grouped into homogeneous regions. Shadow regions that are adjacent to a bright streak (in the CFAR output) towards the sensor are classified as building shadows. Roads are verified using a shape/size criterion. ML segmentation is then repeated for pixels previously misclassified as road and shadow, this time classifying them as grass, bare ground or trees. Tree regions are grown using morphological operations, and verified using a size argument, as well as by the presence of adjoining shadow regions away from the sensor. In the CFAR output, streaks corresponding to buildings are eliminated, and the remaining target pixels are grouped into clusters. In the final step, ML segmentation is repeated, and based on the previous steps, pixels misclassified as shadow, road or tree are re-classified into grass or bare ground.

Examples of results obtained by the approach are shown in Fig. 14.

### Knowledge base

The hierarchy of operators for this application is shown in Fig. 15. The knowledge base consists of the following major components: 21 operators (13 simple and 7 complex), 18 sequential and 2 choice links, and a total of 29 production rules (2 choice, 10 initialization, 6 evaluation, 6 adjustment and 5 repair). The complete knowledge base will not be described in detail in this paper. Instead, some simple examples from the KB are presented to give the reader a feel for the kinds of objects and reasoning involved in a real application.

An example of a complex operator is shown in Fig. 16. The functionality is road verification, which verifies road hypotheses obtained by pixel classification and region growing. This operator has a decomposition into a choice between two simple operators, one of which is shown in Fig. 17. The choice rules for deciding which operator to select are shown in Fig. 18. The reasoning is as follows: in rural areas, roads are likely to have longer unbroken stretches, whereas roads in urban areas have many intersections. Hence an operator for verifying road hypotheses in rural areas should use length as a criterion.

The rules for initializing the parameter "PFA" (probability of false alarm) for the operator "o-cfar" are shown in Fig. 19. This operator is used to detect targets in a SAR image. The

parameter PFA is a threshold which determines the number of bright pixels that are classified as target pixels. The higher the PFA, the more likely it is that a given pixel is classified as a target pixel. The rules for evaluating this operator are shown in Fig. 20. The user is asked to judge if the results of target detection are satisfactory. If not, appropriate action is taken via adjustment rules, such as shown in Fig. 21. An example of the entire chain of reasoning is shown in Fig. 22.

## 6 Example: Vehicle detection

The methodology discussed in Section 4 has also been applied to the detection of vehicles in aerial imagery. We have used a simplified version of the Vehicle Detector developed at the University of Maryland [3], which detects and approximately localizes vehicles of a specified size and

    adjustment-step PFA 80,
    increase PFA

```

Figure 21: Examples of adjustment rules

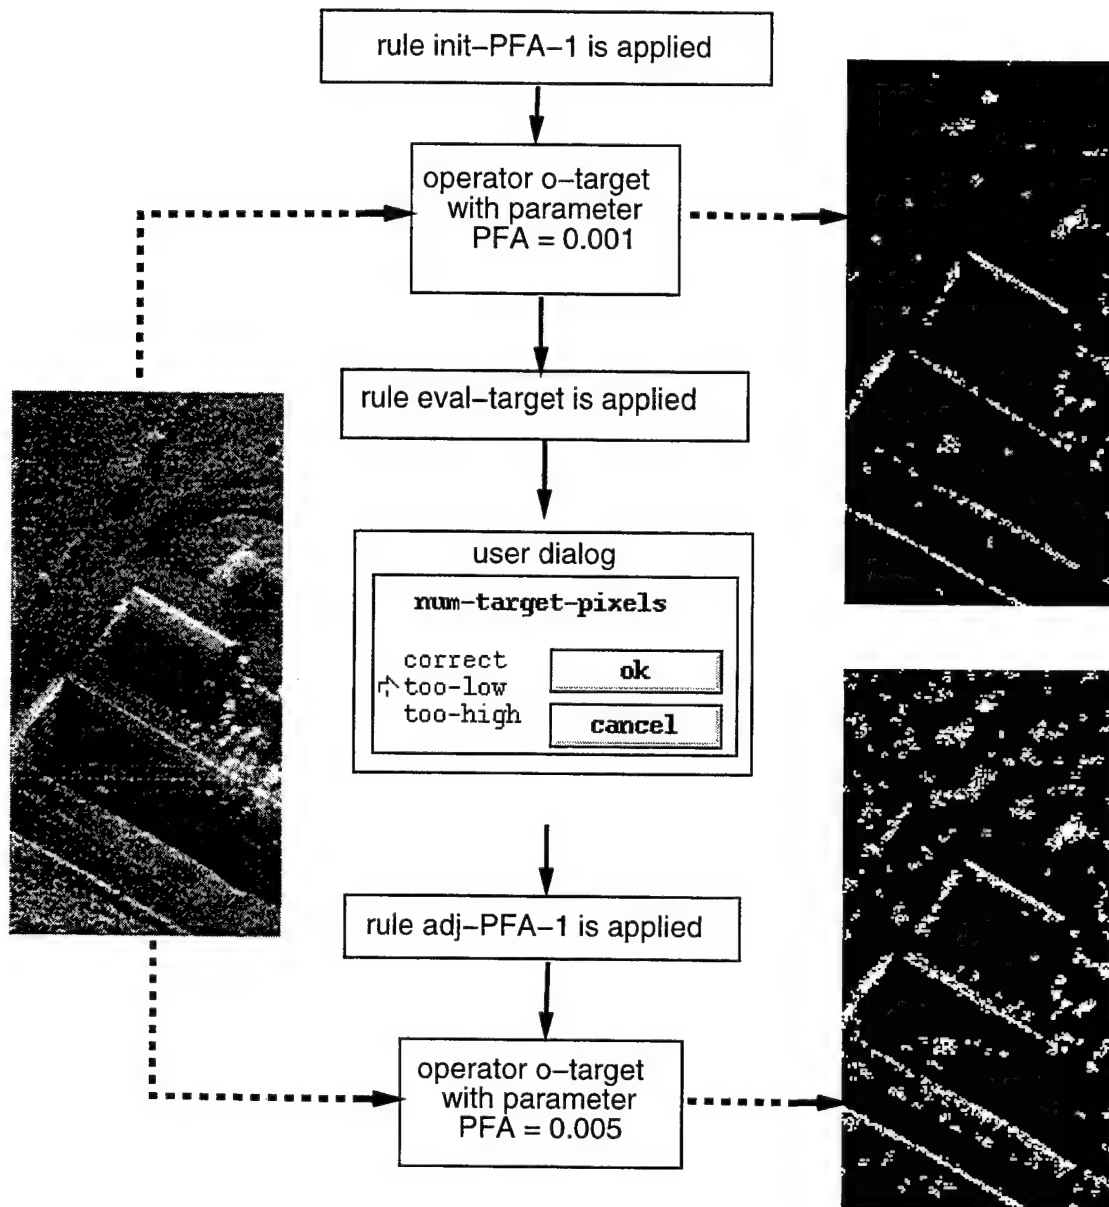

Figure 22: Example of the reasoning used by the control engine. The initial choice of the parameter PFA is 0.001. The operator is executed, and the user examines the result and judges the number of target pixels to be too low. The parameter is then adjusted to 0.005, and the operator is re-executed.

orientation. Our objective here is to demonstrate the application of the approach presented in this paper to a simple existing vision application. We do not attempt to improve on the underlying application itself in any way. The main stages of processing, shown in Fig. 23, are as follows.

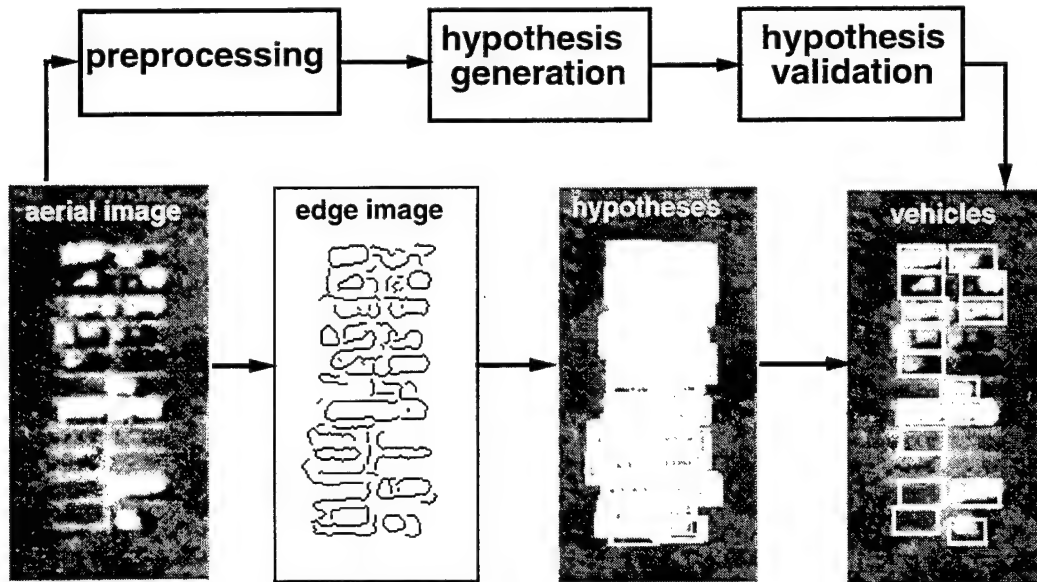

Figure 23: A simplified version of the UMD vehicle detector. The input is an aerial image. Contours are extracted, and vehicle hypotheses are generated. These hypotheses are then validated to obtain the final result.

**Preprocessing:** Edge pixels are extracted using the Canny edge detector. Both gradient magnitude and gradient direction are computed.

**Hypothesis generation:** A modified generalized Hough transform (GHT) is used to locate areas corresponding to centers of candidate vehicles. Edge pixels vote for all possible centers of vehicle contours which contain the pixel. The votes are collected in an accumulator array, and thresholded. The result is a set of hypothesized vehicle centers. Local “rubber-band” contour matching is subsequently applied to reject candidate vehicles which do not have sufficient support boundaries on both sides of the vehicle.

**Hypothesis verification:** This stage resolves spatial conflicts (overlaps) between vehicle hypotheses. This is done in three steps. In the first step, the conflict resolution is done purely on the basis of the distances between the centers of candidate vehicles. If two candidate vehicles are closer than a certain fraction of their width, the one with the greater boundary support is retained. The second step uses the size of the overlap area between two conflicting vehicles as a criterion for rejecting the weaker vehicle. In the final step, the longitudinal distance between adjacent vehicles lying on the same axis is used as a filtering criterion.

## 6.1 Knowledge base

The operator hierarchy for the vehicle detector is shown in Fig. 24. The knowledge base is under development. Currently, it consists of 13 operators (4 complex and 9 terminal), 10 sequential operator links, two choice links, and a total of 37 rules (2 choice, 1 initialization, 11 assessment, 8 adjustment and 15 repair). As the knowledge base for this application is developed further, the number of operators is expected to increase only slightly, whereas the number of rules is expected to increase considerably.

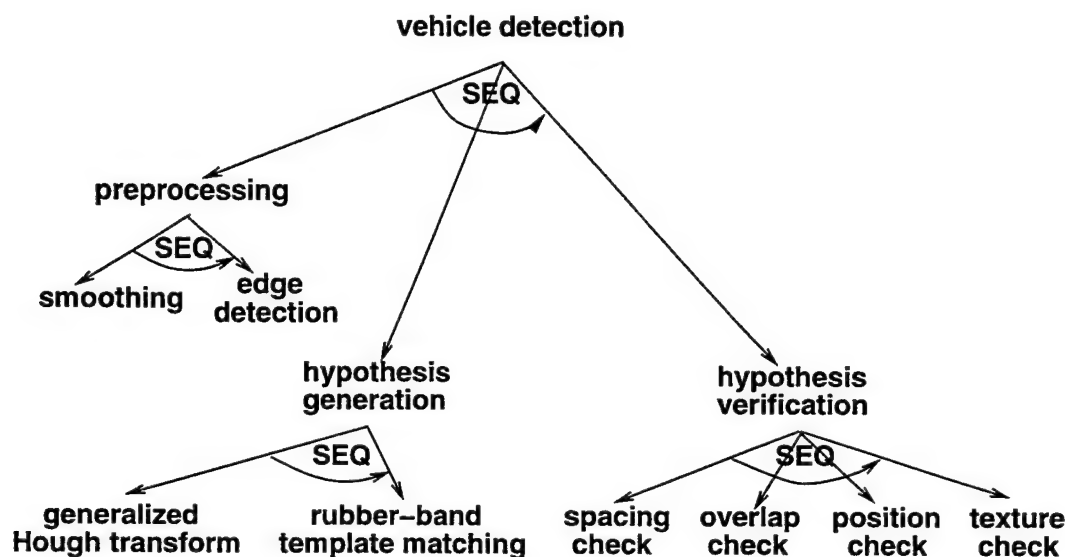

Figure 24: Operator hierarchy for the UMD vehicle detector.

### 6.1.1 Evaluation and repair strategies

As in any target detection application, there are two principal types of errors: missed detections (MDs) and false alarms (FAs). The general objective is to reduce both types of errors as much as possible. In practice, some tradeoff is made between the MD rate and the FA rate. Currently, the user is asked to choose between the responses MD (too many missed detections), FA (too many false alarms) and OK (results are satisfactory). If errors of both kinds are simultaneously present, as is usually the case, the user selects the error which is more significant. If the response is not OK, the user is further queried about the type of MD or FA, as shown in Fig. 25. Currently, MDs due to the following three situations are recognized: vehicles too large or too small, vehicles have low contrast, vehicles too tightly packed. Four types of FAs are handled: multiple hits from the same vehicle, false positives at control lines (the lines used to demarcate the different parking spots), puddles/oil stains mistaken for vehicles, and FAs due to pavement texture. Extensive testing on a diverse set of aerial images will enable us to create a richer taxonomy of errors.

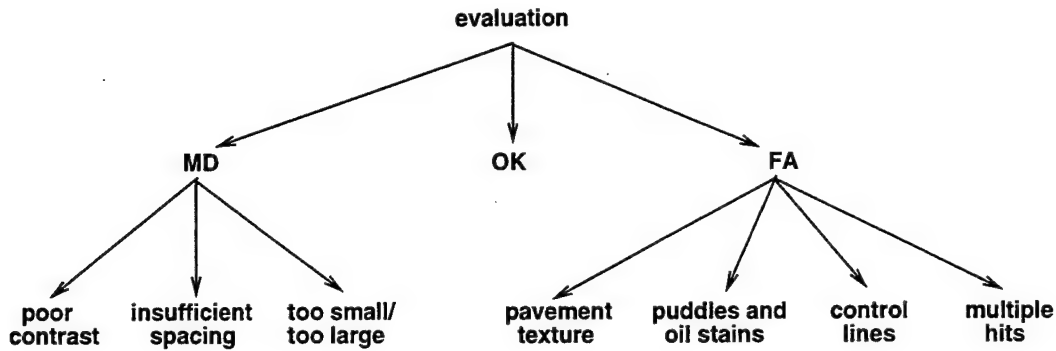

Figure 25: User evaluation of the UMD vehicle detector. The user looks at the result, and judges if there are missed detections (MDs) or false alarms (FAs), and if so, of what type.

The repair mechanism has a nested structure, and is interleaved with the evaluation mechanism. For every allowed error subtype there are one or more repair strategies. The repair strategies are tried one after the other until either the error disappears or the strategies are exhausted. An example is shown in Figure 26. The first run of the system produces the result shown in the first box in the second row. Evaluation rules are fired, asking the user to judge this result. The user indicates that there seem to be false alarms, possibly due to control lines on the parking area. This triggers repair rules, which successively transmit this judgment to the operator “verify-hypotheses” and then to “check-texture”, which is responsible for filtering out such false detections. An adjustment rule in “check-texture” is then applied, adjusting a parameter “contrast-threshold” from 5 to 15. This parameter is the minimum allowable difference in mean grey level between a candidate vehicle and its background. Raising this threshold eliminates the false alarms caused by the control lines, producing the result shown in the first box of the third row. The user evaluates this result again, judging it to have too many missed detections, possibly due to the vehicles being too close together. This judgment triggers a sequence of repair and adjustment rules, resulting in the decrement of a parameter which specifies the factor by which vehicles have to be scaled before deciding that they overlap. This allows candidate vehicles spaced closer together to be judged as non-overlapping, and hence acceptable. The final result, which the user judges to be “OK”, is shown in the first box on the last row.

data/result	user feedback	some of the rules applied	actions taken
		choice rules initialization rules	based on contextual information, appropriate operators are selected and initialized. The selected operators are executed.
	false alarms ( control lines )	(repair rule of operator detect-vehicles) if there are FAs due to control lines, inform operator verify-hypotheses (repair rule of operator verify-hypotheses) if there are FAs due to control lines, inform operator check-texture (adjustment rule of operator check-texture) if there are too many FAs, increase parameter contrast-threshold	The parameter "contrast-threshold" of the operator "check-texture" is increased from 5 to 15. The operator "check-texture" is re-executed.
	missed detections (insufficient spacing)	(repair rule of operator detect-vehicles) if there are MDs due to insufficient spacing, inform operator verify-hypotheses (repair rule of operator verify-hypotheses) if there are MDs due to insufficient spacing, inform operator check-overlap (adjustment rule of operator check-overlap) if there are too many MDs, decrease parameter overlap-threshold	The parameter "overlap-threshold" of the operator "check-overlap" is decreased from 1.0 to 0.8. Operators "check-overlap" and "check-texture" are re-executed.
	OK!		

Figure 1: Example of repair strategy.

## 7 Conclusions and future work

This paper has presented a methodology for adding flexibility and convenience to an existing vision system by integrating the vision specialist's knowledge into it using a knowledge-based architecture. The proposed methodology assumes that the vision system has a non-empty operating region at which it yields satisfactory results. It imitates the strategy of the specialist in reaching a point in this region from a given or default setting. The system can thus self-tune in response to the user's evaluations. This type of system will be of immense value in making the full power of vision algorithms available to end-users.

Our future work will focus on the following areas:

**Detecting failure:** Obviously, if no combination of the tuning parameters can yield satisfactory results, neither the specialist nor the self-tuning framework will have any chance of succeeding. On the other hand, if the self-tuning strategy does not capture the full complexity of the specialist's reasoning, it may fail in difficult cases even if a solution exists. Detecting this failure may not always be easy for the user, since the self-tuning strategy may have loops and other complex chains of reasoning. If the system does not solve the problem in a reasonable amount of time, it should be considered as having failed. Experimentation on large and diverse data sets and constant refinement of the knowledge base will ensure that such failures do not occur too often.

**Validity of the model:** Closely related to the problem of detecting failures is the validation of the basic self-tuning model itself. This model assumes that based on certain "symptoms" of the result, a diagnosis can be made as to which parameter (or algorithm) is at fault. As in [7], the vision system is assumed to possess a "Markovian" property, which allows order-independent and mutually independent parameter tuning. The problem of parameter tuning is essentially ill-posed: there may be many more parameters than symptoms, and a one-to-one mapping may not be easy to establish in all cases. A more complex problem-solving model that takes this into account needs to be investigated.

**Specific evaluations:** Currently, result evaluations are in the form of general remarks about the results obtained, and not about specific portions or objects of the output. Our future work will incorporate some mechanisms for handling specific evaluations. The challenge is in making these mechanisms as application-independent as possible.

**Quantitative performance measures:** There has been some recent work on statistical performance characterization of vision algorithms (e.g. [10]). Integrating this kind of tool into a self-tuning vision architecture, although a challenging task, is a promising area of research, because it would add a quantitative dimension to the result evaluation process.

**Learning:** Machine learning principles can be applied to exploit the wealth of information accumulated over a period of time as the vision system is tested on different data sets [19]. The current implementation of the LAMA platform does not make the operational history of the self-tuning process directly available to the system developer. The availability of this information will enhance machine learning capabilities, and will also be useful in performance analysis.

**Other applications:** The vehicle detection application will be upgraded to use a version capable of detecting vehicles of all sizes and orientations. We propose to test the methodology on other candidate problems such as multisensor registration, and to validate it using large and diverse data sets.

### Acknowledgments

We would like to thank Shyam Kuttikkad, Vasudev Parameswaran, Monique Thonnat, John van den Elst, Hany Tolba and Azriel Rosenfeld for their contributions to the work reported here. We would also like to thank Les Novak of MIT Lincoln Laboratories for providing the SAR image used in one of the examples.

13. ABSTRACT (Maximum 200 words)  We propose a framework for the development of vision systems that incorporate, along with the executable programs, the syntactic, semantic and strategic knowledge required to obtain optimal performance. In this approach, the user provides the input data, specifies the vision task to be performed, and then provides feedback in the form of qualitative evaluations of the result(s) obtained. These assessments are interpreted in a knowledge-based framework to automatically select algorithms and set parameters until results of the desired quality are obtained. In this manner the vision system is given the capacity to tune itself for optimal performance. A system thus trained on a small subset of the input data can then be run autonomously on the remaining data in a batch mode. This approach is illustrated on two real applications, analysis of Synthetic Aperture Radar (SAR) imagery, and detection of vehicles in aerial photographs.

## GENERAL INSTRUCTIONS FOR COMPLETING SF 298

The Report Documentation Page (RDP) is used in announcing and cataloging reports. It is important that this information be consistent with the rest of the report, particularly the cover and title page. Instructions for filling in each block of the form follow. It is important to *stay within the lines* to meet *optical scanning requirements*.

**Block 1. Agency Use Only (Leave blank).**

**Block 2. Report Date.** Full publication date including day, month, and year, if available (e.g. 1 Jan 88). Must cite at least the year.

**Block 3. Type of Report and Dates Covered.** State whether report is interim, final, etc. If applicable, enter inclusive report dates (e.g. 10 Jun 87 - 30 Jun 88).

**Block 4. Title and Subtitle.** A title is taken from the part of the report that provides the most meaningful and complete information. When a report is prepared in more than one volume, repeat the primary title, add volume number, and include subtitle for the specific volume. On classified documents enter the title classification in parentheses.

**Block 5. Funding Numbers.** To include contract and grant numbers; may include program element number(s), project number(s), task number(s), and work unit number(s). Use the following labels:

C - Contract	PR - Project
G - Grant	TA - Task
PE - Program Element	WU - Work Unit Accession No.

**Block 6. Author(s).** Name(s) of person(s) responsible for writing the report, performing the research, or credited with the content of the report. If editor or compiler, this should follow the name(s).

**Block 7. Performing Organization Name(s) and Address(es).** Self-explanatory.

**Block 8. Performing Organization Report Number.** Enter the unique alphanumeric report number(s) assigned by the organization performing the report.

**Block 9. Sponsoring/Monitoring Agency Name(s) and Address(es).** Self-explanatory.

**Block 10. Sponsoring/Monitoring Agency Report Number.** (If known)

**Block 11. Supplementary Notes.** Enter information not included elsewhere such as: Prepared in cooperation with...; Trans. of...; To be published in.... When a report is revised, include a statement whether the new report supersedes or supplements the older report.

**Block 12a. Distribution/Availability Statement.** Denotes public availability or limitations. Cite any availability to the public. Enter additional limitations or special markings in all capitals (e.g. NOFORN, REL, ITAR).

DOD - See DoDD 5230.24, "Distribution Statements on Technical Documents."

DOE - See authorities.

NASA - See Handbook NHB 2200.2.

NTIS - Leave blank.

**Block 12b. Distribution Code.**

DOD - Leave blank.

DOE - Enter DOE distribution categories from the Standard Distribution for Unclassified Scientific and Technical Reports.

NASA - Leave blank.

NTIS - Leave blank.

**Block 13. Abstract.** Include a brief (*Maximum 200 words*) factual summary of the most significant information contained in the report.

**Block 14. Subject Terms.** Keywords or phrases identifying major subjects in the report.

**Block 15. Number of Pages.** Enter the total number of pages.

**Block 16. Price Code.** Enter appropriate price code (*NTIS only*).

**Blocks 17. - 19. Security Classifications.** Self-explanatory. Enter U.S. Security Classification in accordance with U.S. Security Regulations (i.e., UNCLASSIFIED). If form contains classified information, stamp classification on the top and bottom of the page.

**Block 20. Limitation of Abstract.** This block must be completed to assign a limitation to the abstract. Enter either UL (unlimited) or SAR (same as report). An entry in this block is necessary if the abstract is to be limited. If blank, the abstract is assumed to be unlimited.
